

1   **Abstract**

2           A method and apparatus for object detection and ranging is disclosed. An  
3   returned signal is sequentially received by one of several sensors mounted on a host  
4   vehicle. Each one in turn initiates successive sampling to collect a series of returned  
5   signal values, which are then compared with corresponding threshold values previously  
6   saved in a memory device to determine whether any object is in the way of the vehicle  
7   backing up and also to estimate the relative distance from the object. The control circuit  
8   in accordance with the invention includes a processor, which together with a channel  
9   selector establishes a sequence of signal transmission and reception each time by one of  
10   several sensors. A sampled signal is first passed through an A/D converter to become  
11   digital, and then it is input to the processor for object detection and ranging computation.
